(Received 9 February 2017; accepted 14 April 2017; published online 2 May 2017)

Understanding high-field amplitude electromagnetic heat loss phenomena is of great importance, in particular, in the biomedical field, because the heat-delivery treatment plans might rely on analytical models that are only valid at low field amplitudes. Here, we develop a nonlinear response model valid for single-domain nanoparticles of larger particle sizes and higher field amplitudes in comparison to the linear response theory. A nonlinear magnetization expression and a generalized heat loss power equation are obtained and compared with the exact solution of the stochastic Landau-Lifshitz-Gilbert equation assuming the giant-spin hypothesis. The model is valid within the hyperthermia therapeutic window and predicts a shift of optimum particle size and distinct heat loss field amplitude exponents, which is often obtained experimentally using a phenomenological allometric function. Experimental hyperthermia data with distinct ferrite-based nanoparticles and third harmonic magnetization data support the nonlinear model, which also has implications for magnetic particle imaging and magnetic thermometry. I. INTRODUCTION

The response of nanomaterials to alternating electromagnetic fields is of great importance in the biomedical field, where new approaches to treat diseases are under development. One of the most innovative and important applications is related to heat delivery through the interaction of nanomaterials with electromagnetic fields. This heat delivery method can be used to release drugs,1 activate biological processes,2–4 and even treat tumors.5–9 Indeed, using Maxwell’s equations and the first law of thermodynamics, one finds that the heat loss per unit volume per cycle is given by

\[
\frac{1}{V} \int_{\text{cycle}} \delta Q = \oint_{\text{cycle}} \vec{E} \cdot \vec{J} \, dt - \oint_{\text{cycle}} \vec{P} \cdot d\vec{E} - \oint_{\text{cycle}} \mu_0 \vec{M} \cdot d\vec{H},
\]

where \( V \) is the nanomaterial volume, \( Q \) is the heat loss, \( \vec{E} \) is the electric field, \( \vec{J} \) is the free volumetric density current, \( \vec{P} \) is the electric polarization, \( \mu_0 \) is the vacuum magnetic permeability, \( \vec{M} \) is the magnetization, and \( \vec{H} \) is the magnetic field. The first term in equation (1) corresponds to the “free-current” loss, whereas the last two describe dielectric and magnetic losses.

The “free-current” loss term has an important impact on the biomedical application, because it is related to a biological constraint. This term states that the frequency (\( f \)) and magnitude of the alternating magnetic fields need to be lower than a critical value in order to inhibit possibly harmful ionic currents in the patient’s body.7 For instance, for a frequency of 100 kHz the maximum field amplitude is in the order of 20.8 kA/m (261 Oe) for a single air-core coil radius of 0.035 m (expected dimension for breast cancer application).10 Note that this value is higher than the one usually reported (order of 4.9 kA/m) only because the estimation of Atkinson used a coil radius of 0.150 m. Since the free current loss is proportional to the square of the distance from the coil axis, an estimation of the critical field for a given coil radius (\( r \)) might be obtained from \( H_f < (0.150/r) \times 4.85 \times 10^5 \text{ kA}/(\text{m} \times \text{s}) \). Figure 1 shows the biological critical field as a function of field frequency in the usual therapeutic hyperthermia range using Atkinson’s criteria,7,10,11 which indicates that the higher the frequency the lower is this field (the parameters used to generate the curve are presented in the figure captions).

On the other hand, the last terms of Eq. (1), which represent hysteretic losses, have been the subject of analytical models within the Linear Response Theory (LRT) and were used to estimate the optimal particle size and understand particle-particle interaction effects and maximum heat generation for hyperthermia.12–15 Curiously, most LRT studies from the literature do not discuss a fundamental limitation of the model, namely, that it is only valid at the low particle size range and low field amplitudes.

In Fig. 1, we show the range of validity of the LRT, which, as can be seen, is far below the typical fields used for hyperthermia studies. There are several suggestions for identifying this limit. For example, Carrey et al.16 found that the

---

1Author to whom correspondence should be addressed. Electronic mail: mscarriao@ufg.br
spin hypothesis that considers the particle as a uniform single-domain in which all spins rotate coherently, which allows one to use the Fokker-Planck equation that describes the magnetic moment orientational distribution function. One can then show that this leads to an infinite hierarchy of equations, which can be solved numerically to find the magnetic moment response of the nanoparticle.24–27 The method is valid for any field amplitude, but due to its mathematical complexity, it does not yield simple analytical expressions that could be useful in the applied field.

Indeed, the field and frequency-dependence of heat loss in magnetic materials have been attracting the attention for a long time due to technological applications.28 In general, the loss in magnetic materials can show several contributions, spanning from eddy currents (that scales with $f^2H^2$), anomalous eddy current contributions (due to complex domain wall dynamics which scales with $f^{3/2}H^{3/2}$) up to multidomain magnetic hysteresis contribution. The latter term can be explained using the Rayleigh correction to the magnetic permeability and reveals a power loss scaling with $fH^2$. This type of behavior had been reported before in magnetic nanoparticle hyperthermia experiments.29 The authors suggest that this can be explained by the existence of large particles in the sample.29 So, multidomain particles could be relevant to heat generation through domain wall motion loss. However, for most used magnetic fluid samples, multidomain particles are not expected. For example, in magnetite nanoparticles the single-domain limit is around 80 nm.30 Moreover, from the theoretical point of view, Carrey et al. investigated the SLP field exponent using numerical simulations of the SLLG equation (see Fig. 7 of Ref. 16). The authors found theoretically that this exponent is size dependent and showed values below or higher than 2. This type of behavior was found experimentally by Verde et al.17,29 However, in both works, no simple analytical expression was used to explain this behavior. From the experimental point of view, after obtaining the SLP data of the samples as a function of the applied alternating field, it is common to try to describe the heating efficiency in terms of a field exponent, i.e., one might try to fit the data with an allometric expression as $SLP = aH^\nu$, where $a$ is a constant and $\nu$ the field exponent. If this exponent is equal to 2, one might argue that the sample is within the linear response regime. But, once more, this behavior cannot be explained, only phenomenologically described.

Here, we show that through a modification of Bloch’s equation, which is linear with respect to the magnetization, one is able to obtain a heat loss expression valid beyond the LRT. Indeed, different from other works from the literature, we demonstrate that even the linear frequency term has higher order field contributions. Also, our model introduces a nonlinear frequency term which adequately describes the magnetic response within the hyperthermia therapeutic window. The validity of the model is explicitly tested by comparing it with numerical simulations of the SLLG approach. In addition, we included experimental magnetic hyperthermia data that support our theoretical findings. Twelve powder samples were studied, including cobalt-ferrite, copper-ferrite, nickel-ferrite, maghemite, and manganese-ferrite (doped with Zn or Co and also undoped) based nanoparticles. The analytical
nonlinear response model is believed to be useful not only for improving our understanding of magnetic losses but also may impact other related areas, which could benefit from analytical expressions, as for example, magnetic particle imaging (MPI)\textsuperscript{31,32} and magnetic nanothermometry (MNT).\textsuperscript{33,34}

The article is organized as follows: In Section II, we develop the proposed nonlinear response model (NLRT). In Section III, we present the experimental procedure, i.e., the synthesis and characterization of magnetic nanoparticles. In Section IV, we discuss all the theoretical and experimental results. Here, we focus on magnetic nanoparticle hyperthermia but also compare our model with the third-harmonic magnetic particle imaging data from the literature. Finally, in Section V we summarize our findings. In the Appendix, we discuss several models from the literature. In particular, we review the linear response theory (LRT), the nonlinear Ferguson-Krishnan model (FK) (usually applied in magnetic particle imaging), the perturbation method developed by Raikher and Stepanov (RS model), and finally the stochastic Landau-Lifshitz-Gilbert model (SLLG), which is expected to be the exact solution of the magnetic response of the nanoparticle at alternating field conditions. All the models are critically compared showing the necessity of developing a simple nonlinear analytical model.

II. THEORETICAL MODEL

In this section, we present our nonlinear response model. First, we include the magnetic anisotropy energy term in the longitudinal case, which allows us to obtain any quasi-static (QS) (equilibrium) susceptibility terms. Those expressions are related to the cubic harmonic calculation, which is an important parameter for magnetic particle imaging application. In this section, we present our nonlinear response model. In particular, we discuss several models from the literature. In particular, we introduce the magnetic anisotropy energy term in the longitudinal case, which allows us to obtain any quasi-static (QS) (equilibrium) susceptibility terms. Those expressions are related to the cubic harmonic calculation, which is an important parameter for magnetic particle imaging application.

A. Quasi-static longitudinal case

For a uniaxial magnetic nanoparticle in the longitudinal case, the average magnetization is obtained from

\[
\frac{M}{M_S} = \langle \cos \theta \rangle = \frac{\int_0^\pi \cos \theta e^{\sigma \cos^2 \theta + \xi \cos \theta} \sin \theta d\theta}{\int_0^\pi e^{\sigma \cos^2 \theta + \xi \cos \theta} \sin \theta d\theta}.
\]

For \( \sigma > 0 \), one can show that the longitudinal magnetization is \textsuperscript{35}

\[
M = M_S \left( \frac{2 \sinh(\xi)}{\sqrt{\sigma \pi}} \right) \left( \text{erf} \left[ i \left( \sqrt{\sigma + \frac{\xi}{2 \sqrt{\sigma}}} \right) \right] + \text{erf} \left[ i \left( \sqrt{\sigma - \frac{\xi}{2 \sqrt{\sigma}}} \right) \right] - \frac{\xi}{2 \sigma} \right).
\]

Expanding the longitudinal magnetization in a Taylor series:

\[
M = M_S \left[ \frac{i e^x}{\sqrt{\sigma \pi} \text{erf} \left( i \sqrt{\sigma} \right)} - \frac{1}{2 \sigma} \right] + M_S \left[ \frac{2 e^x (6 \sigma e^x + i \sqrt{\sigma} (2 \sigma + 3) \text{erf} \left( i \sqrt{\sigma} \right))}{12 \pi (\text{erf} \left( i \sqrt{\sigma} \right))^2} \right] \xi + \cdots
\]

\[
= \chi_{QS,1} H + \chi_{QS,3} H^3 + \cdots,
\]

where \( \text{erf}(iz) = (2i / \sqrt{\pi}) \int_0^z e^{i \tau} d\tau \) and \( \chi_{QS,3} < 0 \). Note that all \( \chi_{QS,n} \) are real. In the Appendix, we discuss how this case differs from the Langevin model. In particular, Fig. 5(b) shows the ratio of the \( \chi_{QS,n} / \chi_{L,n} \) up to the fifth-order \( (n = 5) \). The longitudinal linear susceptibility \( \chi_{L,1} \) calculation demonstrates that in the absence of (or very low) magnetic anisotropy, the susceptibility approaches the expected Langevin result. On the other hand, in the high anisotropy limit, the linear ratio approaches 3, which indicates that the longitudinal result tends to the Ising result, as expected in this case. Other ratios are also shown in the Appendix. Therefore, we can conclude that in general it is of great importance to include the anisotropy term when investigating the magnetic response of nanoparticles.

B. Nonlinear response model

As in the LRT model, let us assume that a magnetic particle is subjected to a harmonic field and that the projection of the magnetization, \( M(t) \), in the field direction satisfies the Bloch equation, i.e.

\[
\tau \left( \frac{dM}{dt} \right) + M = f(t),
\]

where \( \tau \) is the relaxation time and \( f(t) \) is a function of the alternating field. Hence, it will be periodic, i.e., \( f(t) = f(t + 2\pi / \omega) \). Also, in general one might represent \( f(t) = \chi_1 H(t) + \chi_3 H(t)^3 + \cdots \), where \( \chi_n \) is the \( n \)-th order magnetic susceptibility. The LRT corresponds to considering just the first term in \( f(t) \). The nonlinear response under Bloch’s assumption may be computed as follows. In general, \( f(t) \) is a function of \( H(t) \) so it may be expanded in a cosine series as \( f(t) = \sum_{n=1}^\infty c_n \cos(n \omega t) \) for certain coefficients \( c_n \), which can be easily identified by expanding \( f(t) \) in terms of \( \cos(n \omega t) \) (another alternative way to obtain those coefficients is using the integrating factor method directly to Bloch’s equation). The steady-state solution of the Bloch equation is therefore

\[
M(t) = \sum_{n=1}^\infty c_n \cos(n \omega t + \phi_n) \frac{\sin n \omega t}{1 + (n \omega t)^2}
\]

In this approach, the corresponding SLP is

\[
\text{SLP} = \frac{\pi f}{\rho} \frac{\omega t}{1 + (\omega t)^2} C_1
\]

\[
= \frac{\pi f}{\rho} \frac{\omega t}{1 + (\omega t)^2} \left( \chi_1 H_0^1 + \frac{3}{4} \chi_3 H_0^1 + \frac{5}{8} \chi_5 H_0^1 + \cdots \right).
\]
This means that other terms are negligible in comparison to $c_1(H_0)$. This comes from the fact that in the heat loss integral only the terms obtained from $n = 1$ are nonzero. Note that the first term corresponds to the usual Debye model, if one assumes that $\chi_1 = \chi_{QS,1}$, i.e., that $\chi_1$ is the quasi-static limit linear coefficient. Also, it might be important to mention that the existence of the higher order field dependent terms indicates a correction not reported before in the literature. As for instance, if one uses the magnetization equation of the RS model, only the quadratic field term appears. The same approach can also be used in the dielectric loss case, for example, the electric field dependence dielectric loss of glycerol (see the inset of Fig. 3 of Ref. 19).

According to Equation (6), the Bloch solution for the magnetization $M(t)$ up to cubic terms in the field is

$$M(t) = \left(\chi_1 H_0 + \frac{3}{4} \chi_3 H_0^2\right) \frac{\cos(\omega t) + \omega t \sin(\omega t)}{1 + (\omega t)^2} + \frac{\chi_3 H_0^2 \cos(3\omega t) + 3\omega t \sin(3\omega t)}{1 + (3\omega t)^2},$$  

(8)

where $\chi_n$ are the $n$th-order magnetic susceptibility coefficients. From the above equation, it is clear that higher-order terms are also relevant to the magnetization dynamics. As for instance, this nonlinearity effect can be identified even for the first harmonic contribution, which shows higher field order terms.

In addition, if $\omega t \ll 1$ one may write the magnetization (considering higher-order terms in $f(t)$) as $M(t) = \chi_1 H_0 \cos(\omega t) + \chi_3 H_0^2 \cos(\omega t)^3 + \ldots$. For the sake of argument, if one assumes that the $n$th-order susceptibility terms are equal to the quasi-static terms ($\omega \rightarrow 0$) and that the nanoparticle is in the superparamagnetic regime, then $M(t)/M_s = L(\xi \cos(\omega t)) + O(\omega t)$. Note that the first term of this equation has been used systematically in both magnetic particle imaging (MPI) and magnetic nanothermometry (MNT). In MNT, the magnetization expression was shown to be useful only in the low frequency range, which is easily explained by our model due to the range of validity of the latter expression. Moreover, in MPI the magnetization is similar, but not identical to our model, and differs mainly due to the term $n\omega t$ and that the latter assumes quasi-static susceptibility terms and superparamagnetic particle. As a consequence, our model gives different higher-order harmonic magnetization terms and might represent better the experimental MPI data. Our model gives a similar expression to Ref. 36 for the heat loss if we assume that $\chi_n = \chi_{QS,n}$. However, this approximation does not represent correctly the magnetization dynamics.

Further, Eq. (7) shows that the Bloch equation predicts the same frequency dependence as the LRT, which will result in elliptical-like hysteresis curves that are in disagreement with experiment. The reason for this discrepancy is that Bloch’s equation is linear, whereas the underlying physical phenomenon is not (see the Appendix). One way to circumvent this is to assume that the coefficients $\chi_n$ depend explicitly on $\omega$. The exact form of this dependence is problem specific, but it must be such that when $\omega \rightarrow 0$, one recovers the equilibrium nonlinear susceptibilities. The heuristic improvement approach, also used by others, but in this work not based on a rigorous mathematical approach, is able to better represent the magnetization dynamics.

So, to correct for the aforementioned deficiency of the Bloch approach, we replace $\chi_n$ with a frequency dependent function and compare the approximation with exact results, which are obtained for the longitudinal case using the SLLG model. In this strategy, we wrote $\chi_n = \chi_{QS,n} g_n$, where $g_n$ is a function of the frequency. The quasi-static susceptibility coefficients were obtained from the series expansion of the quasi-static longitudinal solution. Also, from our assumption, it is obvious that one should have $g_n(\omega \tau \rightarrow 0) = 1$. Moreover, for the first term we should have $g_1 = 1$, which corresponds to the LRT result. For the cubic term we found that

$$\chi_3 = \chi_{QS,3} \frac{3 - (\omega t)^2}{3(1 + (\omega t)^2)}.$$  

(9)

Similar to the RS model, the magnetization can be written in the same functional form as Eq. (A11) in the Appendix. However, now the real susceptibility terms are

$$\chi_1 = \frac{\chi_{QS,1}}{1 + (\omega t)^2} + \frac{1}{4} \frac{H_0^2 \chi_{QS,3}}{1 + (\omega t)^2},$$  

(10)

$$\chi_3 = \frac{1}{12} \frac{\chi_{QS,3}}{(1 + (\omega t)^2)(1 + (3\omega t)^2)},$$  

(11)

while the imaginary terms are $\chi''_n = \omega t \chi'_n$ and $\chi''_3 = 3\omega t \chi'_3$. Those results indicate that the susceptibility terms are distinct from the RS model (see Eqs. (A9) and (A10) in the Appendix), even though the quasi-static susceptibility coefficients give the same result. Also, the linear susceptibility term shows a nonlinear field and frequency contribution, which was absent in other models.

So, returning to the heat loss integral (Eq. (A4), in the Appendix) and using the cubic magnetization (Eq. (8)) with this correction (Eq. (9)), the new expression for SLP is now given by

$$SLP = \mu_0 \mu_r f_0 \frac{f_0^2}{\rho} \left[ \chi_{QS,1} \omega t \frac{H_0^2}{1 + (\omega t)^2} + \frac{1}{4} \frac{H_0^2 \chi_{QS,3}}{1 + (\omega t)^2} \right] \frac{3 - (\omega t)^2}{1 + (\omega t)^2}.$$  

(12)

In addition, because we also investigate soft-magnetic nanomaterials (low $\sigma$), the empirical uniaxial relaxation time expression, valid for any anisotropy value, has been considered

$$\tau = \tau_0 (e^\sigma - 1) \left[ 2^\sigma + \frac{2^\sigma^{3/2}}{\sqrt{\pi}(1 + \sigma)} \right]^{-1}.$$  

(13)

It is important to notice that the proposed model takes into account exclusively the Néel relaxation process. This
mechanism is the most relevant in powder samples, as the ones studied in this article, in which the nanoparticles cannot rotate. Note that, powder samples might be more closely related to cancer treatment application, since during endocytosis (nanoparticle internalization into cells) the nanoparticles are found packed (aggregated) inside vesicles (endosomes), which is a particle arrangement situation that inhibits rotation. However, it is possible to develop a similar model to describe the Brownian relaxation process (also named viscous mechanism).\(^\text{39-41}\) But, because the \(g_3\) expression was obtained by comparison with SLLG, Eq. (9) would not necessarily be valid anymore in such a situation. So, one might not be able to use the present model just considering the Brownian relaxation (instead of the Neel one). Although the viscous mechanism is an important issue, especially under flow conditions, this subject is beyond the objective of the present article. Further, readers interested in this type of analysis should check Refs. \(^\text{39-42}\).

### C. Cubic harmonic MPI signal

Besides magnetic hyperthermia, the present model might be useful for magnetic particle imaging (MPI) too. MPI is a nonionizing imaging technique, introduced in 2005 by Gleich and Weizenecker,\(^\text{31}\) which is capable of imaging magnetic tracers through the nonlinear magnetic response of magnetic nanoparticles. In MPI, a DC plus an AC field are applied to the magnetic material in such a way to create a free field point volume where the nanoparticles can respond to the ac field excitation. The magnetic response signal can then be measured using detector coils. The received voltage by the detector coil is

\[
    u = -\mu_0 \int \left( S_0(x) \frac{\partial M(x,t)}{\partial t} \right) dV,
\]

where \(S_0\) is the coil sensitivity (assumed to be \(\mu_0 S_0 = 2.25 \text{ mT} / \text{A}\)) and the integration is over the magnetic material. The MPI third harmonic magnetization signal per unit volume \(\text{emf}_{3\text{em}}\) is defined as the module of the Discrete Fourier Transform given by

\[
    \text{emf}_{3\text{em}} = \mu_0 S_0 |DFT[\mu_3]|,
\]

after characterizing by X-ray diffraction (XRD) and vibrating sample magnetometer (VSM). All chemical reagents (FeCl\(_3\), H\(_2\)O, MnCl\(_2\), 4H\(_2\)O, ZnCl\(_2\), CoCl\(_2\), 6H\(_2\)O), citric acid trisodium salt—Na\(_2\)C\(_9\)H\(_6\)O\(_7\), methylamine—CH\(_3\)NH\(_2\), and acetone—CH\(_3\)(COCH\(_3\)) were purchased with analytical quality and used without any further purification. In a typical approach, Mn\(_{0.75}\)(Zn or Co)\(_{0.25}\)Fe\(_2\)O\(_4\) magnetic nanoparticles were prepared as follows: adequate amounts of 1.0 mol/l metal stock solutions were diluted with 40.0 ml of distilled water to form a precursor solution containing 10.0 mmol of Fe\(^{3+}\), 3.75 mmol of Mn\(^{2+}\), and 1.25 mmol of Zn\(^{2+}\) or Co\(^{2+}\). Thus, 120 mmol of methylamine at 40% (w/w) were quickly poured into the stock solution under vigorous stirring for 10 min and then transferred into a 120 ml Teflon-sealed autoclave and heated up to 160°C for 6 h. After cooling to room temperature, the precipitate was separated by magnetic decantation, washed with H\(_2\)O three times, and re-dispersed in 50.0 ml of water. Then, 4.0 mmol of citric acid trisodium salt was added into the solution which was heated up to 80°C for 60 min. After adjusting the pH of slurry to 7.0 and washing with acetone three times, the precipitate was re-dispersed in 50.0 ml of water to form a magnetic sol, after evaporating residual acetone. Thus, a size-sorting process was done by adding 1 g of NaCl to the as-prepared magnetic sol.\(^\text{43}\) 5 min afterwards under a permanent magnet (NdFeB), addition of salt induced a phase transition and formed an upper (bottom) sol phase with populations of smaller (larger) nanoparticles. Once separated, precipitate of each phase was washed twice with a mixture water/acetone 1:10 (volume/volume) and, after evaporating residual acetone, nanoparticles were re-dispersed in water. This procedure was repeated several times. Powders were obtained from evaporation of sols at 55°C for 8 h. Details about cobalt-ferrite samples can be found in Ref. \(^\text{18}\) and copper-ferrite and nickel-ferrite samples can be found in Ref. \(^\text{17}\).

After the size-sorting process, powder samples were analyzed by XRD (Shimadzu 6000) to separate samples with similar sizes. The previous analysis was performed using the well-known Scherrer equation, which is given by

\[
    D_{\text{XRD}} = \frac{\kappa \lambda}{\beta \cos \psi},
\]

where \(\kappa = 0.89\) is the Scherrer constant, \(\lambda = 0.15406 \text{ nm}\) is the X-ray wavelength, \(\beta\) is the line broadening in radians obtained from the square root of the difference between the square of the experimental width of the most intense peak to the square of silicon width (calibration material), and \(\psi\) is the Bragg angle of the most intense peak (311). This procedure allowed us to select three distinct samples of similar sizes containing MnFe\(_2\)O\(_4\), Mn\(_{0.75}\)Zn\(_{0.25}\)Fe\(_2\)O\(_4\), or Mn\(_{0.75}\)Co\(_{0.25}\)Fe\(_2\)O\(_4\) nanoparticles. All the nanoparticles were surface-coated with citric acid, which guarantees stability at physiological conditions. The samples were also characterized by VSM (ADE Magnetics, model EV9, room temperature measurements, field up to 2T). Table I summarizes the relevant characterization properties of the nanoparticles.

Finally, magnetic hyperthermia data were obtained in two systems, one homemade which operates at 500 kHz and the other from nanoTherics. In particular, the latter system operates in a broad frequency range, spanning from 110 up to 980 kHz. The details about the homemade hyperthermia

system have been described elsewhere. The calorimetric method used to obtain the experimental SLP of the sample used the equation

$$SLP = \frac{C}{m_{\text{NP}}} \left( \frac{dT}{dt} \right)_{\text{max}},$$

(17)

where $C$ is the heat capacity of the sample (here, assumed as the heat capacity of the liquid carrier due to the low concentration of particles), $m_{\text{NP}}$ is the mass of magnetic nanoparticles in unit of grams (obtained from the analysis of the magnetisation curves of the colloid samples), and $T$ is the temperature of the sample measured with a fibre optic thermometer. Note that in the SLP calculation we use the value of the maximum rate of temperature increase ($\left( \frac{dT}{dt} \right)_{\text{max}}$), as discussed previously by others. This method is believed to better estimate SLP than the most common initial-slope procedure that can underestimate this value.

IV. RESULTS AND DISCUSSION

A. Theoretical results

Several experimental results show the existence of an optimal particle size for hyperthermia. This is also contemplated in Eq. (A5) of the Appendix, obtained in LRT, which predicts that this optimal size should occur when $\omega \tau = 1$. This, however, is only true at low field amplitudes. Increasing field amplitude one notices a shift of maximum size towards larger particles in a noninteracting system. This can be easily modelled within LRT using the field dependent magnetization relaxation time. Indeed, such drift becomes clear when $h > 0.04$ (see discussion of Fig. 2(f) below). Further, numerical dynamic hysteresis simulations using the SLLG model or Kinetic Monte Carlo method show that, as the field amplitude increases, the optimal size shifts towards larger particles. It may even disappear, depending (also) on the magnetic anisotropy of the nanoparticle. Most of the above results consider a noninteracting system. However, in colloids, or real in vivo situation, agglomerate formation plays a key role. In this case, it has been shown within LRT that the opposite effect occurs, i.e., increasing the strength of the particle interaction shifts the optimal diameter to lower sizes. The same was found including the particle-particle interaction using a mean field approach to the SLLG model in the low field regime. Notwithstanding, a valuable analytical nonlinear response theoretical model (NLRT) should be able to explain at least some of the features discussed above.

A comparison between the hysteresis curves obtained from the LRT, our NLRT model, and the numerical solution of the SLLG model is shown in Figs. (2(a)–2(d), for distinct $\sigma$ values considering $\sigma r_0 = 10^{-3}$ and $H_0/H_K = 0.1$. It is found that the inclusion of the corrected cubic term leads to a good agreement with the numerical simulations, adequately describing the deviations from the linear response. Note that the agreement is far better than any other model discussed previously (see the Appendix). The LRT model is shown as a dashed line, the exact result using the SLLG equation is shown as dashed-dotted line, while NLRT (considering Eq. (9)) is shown as a solid line. It is very surprising that, with such a simple assumption, an interesting nonlinear effect is obtained able to represent far better the magnetization dynamics. Indeed, we found that the present model works very well close to this limit of anisotropy value ($H_0 \approx 0.14H_K$). It also has a slight frequency dependence which can be monitored by nonphysical results in the magnetization curve or kinks in the SLP versus $\sigma$ curves increasing the field. At higher fields, we observe deviations from the exact solution that might be only addressed if higher-order terms are determined. Nevertheless, as shown in Fig. 1 (see the NLRT line), the range of validity of the model is almost completely within the hyperthermia therapeutic window. This suggests that this model might be applicable for real clinical situations.

Figure 2(e) shows the SLP as a function of $\sigma$ for the LRT (dashed line) and the NLRT (solid line) for distinct field amplitudes. For simplicity, we are not considering the field dependence on the relaxation time. One can clearly observe a shift of the maximum of SLP towards higher particle sizes in the nonlinear case and also a decrease of the maximum SLP value for the NLRT case. The phenomenon is strictly related to the nonlinear effect introduced in the model and not due to the field effect from the relaxation. This result is in accordance with numerical simulations from the literature. On the other hand, Fig. 2(f) also shows SLP as a function of $\sigma$ in both cases, but now investigating the field effect on the relaxation time for $H = 0.09H_K$. Similar behavior to that mentioned before is observed. Nevertheless, in comparison with the LRT, the NLRT-$\tau(H)$ shows a larger size shift. As for instance, the optimum anisotropy term changes from $\sigma_{opt} = 8.1$ for LRT to $\sigma_{opt} = 9.0$ for NLRT-$\tau(H)$, which corresponds to a shift in optimal diameter of the order of 4%.

As discussed, there are other nonlinear models (see the Appendix). In particular, cubic susceptibility expressions using the RS model had been suggested to represent experimental data of noninteracting magnetic nanoparticles. Figure 2(g) shows the cubic susceptibility terms, imaginary and real, for the RS model and the NLRT model as a function of temperature. Here, the parameters used were $d = 11$ nm,
$M_s = 270$ emu/cm$^3$, $K_{cf} = 8 \times 10^4$ erg/cm$^3$, $\alpha = 0.05$, and $\rho = 5$ g/cm$^3$. As found in Ref. 37, the real cubic term in the RS model shows a significant variation as a function of temperature, in particular, in the range below 60 K, where a quite high positive cubic value is found theoretically. It is curious to notice that experimentally such effect has not been observed in Ref. 47 for noninteracting nanoparticle samples. In fact, discrepancies between the RS model and data of Ref. 47 had been attributed to polydispersity and particle-particle interaction effects. Note that the inclusion of such effects could be responsible for some of those differences between theory and data. However, there might be another explanation. As we have just shown, the NLRT model represents far better the magnetization response. Differently from the RS model, the real cubic susceptibility from NLRT does not show such strong positive contribution at low temperatures. As a consequence, it might represent better experimental data. Another point that could be commented about the improvement in the NLRT model in comparison to others is the SLP calculation. Note that in the RS model the SLP calculation, using the magnetization expression of Eq. (A11) in the Appendix, provides the same result as the LRT. So, although the magnetization equations are not the same, the hysteresis area is the same as the LRT case. Again, this is in contradiction with several experimental results. As commented before, experimental results are often fitted using
allometric function $SLP = aH^n$, where an exponent different than 2 indicates a deviation from linear response. An alternative approach is plotting SLP data as a function of quadratic field, where linear behavior is represented by the straight line, obviously. Figure 2(h) shows the SLP as a function of the quadratic field for distinct $\sigma$ values considering the LRT (dash), NLRT (solid), and SLLG (points). Both situations show that depending on the particle size or anisotropy, deviations from the expected quadratic field dependence of the LRT are found. In the low barrier regime ($\sigma < \sigma_{opt}$), i.e., for particle sizes lower than the optimum value, the field dependence exponent is lower than 2. While in the high barrier regime, an exponent higher than 2 is observed. The same behavior is found from SLLG, as expected, since the NLRT model is based on the assumption that SLLG is the exact result. However, because in the NLRT only the cubic term was introduced, deviations between both models are expected for higher fields. The nonlinear regime has been studied experimentally before in Ref. 17, where the transition to the nonlinear regime was explained using the SLLG model, though without any analytical expression. The explanation for such behavior may be understood using Eq. (8). Note that $\chi_{QS} < 0$, so when $\alpha_0 < 1.7$ the high-order contribution term lowers the linear SLP field dependence term. The consequence of this is an apparent field exponent lower than 2. On the other hand, when $\alpha_0 > 1.7$ the higher order SLP term changes sign, which now adds a value to the first order term. In this case, exponents larger than 2 might appear if the field is high enough.

From Fig. 2(h), it is also possible to discuss the difference between NLRT and LRT in terms of error in SLP estimate. Using SLLG (points) as the reference, it is clear that the error depends not only on the field but also on $\sigma$. For instance, for $(H_0/H_K)^5 = 0.008$, NLRT presents an error of $-2.6\%$ when $\sigma = 10$ and $-4.8\%$ when $\sigma = 6$. In this same condition, LRT presents errors of $-18\%$ and $+29\%$, respectively. Note that positive error means an overestimation, while negative is an underestimation. Moreover, returning to Fig. 1 (using the same nanoparticle parameters), for a frequency of 234 kHz and a field of 4.1 kA/m (52 Oe), the LRT error is $+5.9\%$. Increasing the field up to 6.4 kA/m (80 Oe, still in the biologically safe region) this error reaches $+14.6\%$. So, using the LRT model for clinical planning might result in inadequate treatment decisions due to the overestimation of the heat efficiency.

**B. Magnetic hyperthermia evidence**

Evidence of nonlinear behavior is that the SLP field dependence can be found in distinct ferrite-based powder samples. Table I summarizes the parameters obtained from sample analysis. Four sets of samples were studied. The first set is composed of three samples: manganese-ferrite based nanoparticles undoped, doped with zinc, and doped with cobalt. Since samples were produced using the same method and have (approximately) the same magnetization and the same diameter, this set allows the study of anisotropy influence over SLP versus $H$ behavior. The second set is composed of other three samples: cobalt-ferrite, maghemite, and copper-ferrite. These samples have very different magnetization and anisotropy but the same diameter (some results published in Ref. 18). The third set is composed of other three samples of cobalt-ferrite, which have a high anisotropy, with different diameters. And, the last set is composed of three samples of nickel-ferrite, which have a lower anisotropy than cobalt-ferrite, with different diameters.

Magnetic hyperthermia experimental data around 500 kHz are shown in Figs. 3(a), 3(c), 3(e), and 3(g) for powder samples, where we present the SLP as a function of the applied field for distinct ferrite-based samples. Most of the applied fields are above the therapeutical values (see Fig. 1) but are necessary to experimentally observe deviations from LRT. Symbols represent experimental data, while the lines are the fit of the data using the allometric function. First, notice that soft-like materials heat more efficiently at low field amplitudes, in agreement with what was found before experimentally and theoretically.\textsuperscript{15,17,18} This property, although not discussed in this work, is relevant for in vivo applications.\textsuperscript{5} Table I shows the apparent field exponents obtained from this type of phenomenological approach for all the samples, as well Figs. 3(b), 3(d), 3(f), and 3(h), compared with 2 (gray dashed line which represents LRT). The result indicates deviation from linear behavior and the samples show distinct exponents values, depending (probably) on sample anisotropy. The same behavior has been observed with other ferrites.\textsuperscript{17} This behavior is in accordance with our previous theoretical analysis. However, a direct comparison between experimental data and theoretical analysis is complicated by the fact that samples are solid and allow a random anisotropy axis nanoparticle configuration that decreases the equilibrium susceptibility values lowering the SLP.\textsuperscript{17} So, the nanoparticles at this highly packed configuration are at strong interacting conditions, which may affect the magnetic anisotropy.\textsuperscript{15,17} In this case, one cannot use the longitudinal calculation developed in this work for the powder samples, because the quasi-static susceptibility values are now different. Nevertheless, powder configuration inhibits frictional loss contributions due to the Brownian relaxation mechanism\textsuperscript{17,46,49} and a similar behavior for SLP (with distinct absolute values) is also expected.

The NLRT model developed here is valid for $H < 0.14H_K$, where magnetization relaxation mechanisms play a role in the spin reorientation by overcoming the barrier energy. For increasing the field value, one need to use directly the SLLG model, which due to the complexity of the problem does not reveal any simple analytical equation. Nevertheless, a simple approach for qualitative analysis under high field conditions ($H > H_K$) might be achieved using the Stoner-Wohlfarth (SW) model.\textsuperscript{13} As discussed before, because of the samples studied, NLRT as presented here does not take into account the Brownian relaxation mechanism, although it is possible to include this feature using a similar approach.

**C. Magnetic particle imaging evidence**

Figure 4 shows the experimental MPI data of the third harmonic magnetization signal of magnetite nanoparticles of
distinct sizes performed at 250 kHz (see Ref. 36 for details). Spheres correspond to experimental data, while squares are related to the FK model of Ref. 36. Note the logarithmic scale and that we are presenting the data in terms of $r$. Here, we assumed the bulk magnetic anisotropy value, although it is well known that the anisotropy is size dependent. Nevertheless, size dispersity was taken into account. The calculations used a relaxation time valid for any $r$ (Refs. 15 and 38) and parameters from Table I of Ref. 36. Triangles correspond to our polydisperse calculation taking the Discrete Fourier Transform and using Eq. (14) in units of V/g, i.e., taking into account in the calculation of $\text{emf}_{\text{loop}}$, the amount of magnetic material in mass per unit volume. Note that our model represents better the MPI experimental data. Indeed from 10 data points, NLRT is in better agreement with 80% of the data. Better theoretical results might be achievable if the anisotropy of each sample is known, or even more if one is able to take into account possible particle-particle interaction effects due to agglomerate formation. So, it might be fair to say that both hyperthermia and MPI experiments seem to be more adequately described by the NLRT model.

FIG. 3. (a) SLP as a function of the magnetic field for distinct manganese-ferrite nanoparticles around 11 nm in powder configuration at $f=522$ kHz. (b) Apparent SLP field exponent $\nu$ obtained for manganese-ferrite in powder configuration. (c) SLP as a function of the magnetic field for distinct ferrite nanoparticles around 9 nm in powder configuration at $f=500$ kHz. (d) Apparent SLP field exponent $\nu$ obtained for distinct ferrite nanoparticles in powder configuration. (e) SLP as a function of the magnetic field for cobalt-ferrite nanoparticles with distinct sizes in powder configuration at $f=500$ kHz. (f) Apparent SLP field exponent $\nu$ obtained for cobalt-ferrite in powder configuration. (g) SLP as a function of the magnetic field for nickel-ferrite nanoparticles with distinct sizes in powder configuration at $f=500$ kHz. (h) Apparent SLP field exponent $\nu$ obtained for nickel-ferrite in powder configuration. Symbols are data and lines represent the best fit using the allometric function.
Finally, it might be relevant to comment that there is a huge interest of not only delivering heat using magnetic nanoparticle hyperthermia but also monitoring non-invasively heat delivery using magnetic nanoparticles. In order to be successful in such areas, analytical expressions, as the ones derived in this work, that better represent the non-linear response of magnetic nanoparticles, are highly needed. The authors believe that the model developed here might indicate a useful approach towards this important clinical goal.

V. CONCLUSION

In conclusion, a nonlinear response model of magnetic nanoparticles valid for single-domain nanoparticles was developed. The model is valid beyond the linear response theory and showed good agreement with dynamic hysteresis simulations using the stochastic Landau-Lifshitz-Gilbert approach and experimental hyperthermia data for field amplitudes as high as 10% of the magnetic anisotropy field. In particular, a generalized expression for the magnetization and the heat loss efficiency (SLP) were obtained. The model showed many features found experimentally in magnetic hyperthermia and MPI studies, for example, Stoner-Wohlfarth-like dynamic hysteresis curves, distinct SLP field exponents, and optimum hyperthermia nanoparticle size shift, among others. The magnetization expression was critically compared with the ones used in MPI and MNT, from which we were able to identify when some approximations can be used. Moreover, the NLRT was found to be valid mostly within the hyperthermia therapeutic window, which suggests strong applicability in the biomedical field.

APPENDIX: MODELS REVIEW

All the models discussed in this manuscript are valid within the single-domain range. Also, although its suitability to describe nanostructures can be discussed, several models assume the giant-spin hypothesis of Brown, i.e., nanoparticle uniformity and coherent spin rotation. Here, we will consider the case of uniaxial magnetic nanoparticle, where the energy is given by

\[
E = KV \sin^2 \theta - \mu_0 M_S VH \cos(\theta - \varphi). \tag{A1}
\]

The first term is the uniaxial anisotropy energy, while the other is the Zeeman interaction. \(\theta\) represents the angle between the magnetic moment of the nanoparticle and the easy axis direction, while \(\theta - \varphi\) corresponds to the angle between the magnetic dipole and the applied field. It is common to name the longitudinal case as \(\varphi = 0\), which is the case where the field is applied in the anisotropy axis direction.

The simplest quasi-static magnetization model in the literature, named Langevin model, neglects the anisotropy term, which can only be done if the ratio of this anisotropy contribution to the thermal energy is very low. In this case, the magnetization can be calculated from

\[
\frac{M}{M_S} = \cos \theta = \int_0^\pi \cos \theta e^{i \cos \theta} \sin \theta d\theta = L(\xi). \tag{A2}
\]

\[
L(\xi) = \coth(\xi) - 1/\xi
\]

is the Langevin function, whose series expansion to fifth order gives

\[
M = M_S \left( \frac{\xi}{3} - \frac{\xi^3}{45} + \frac{2\xi^5}{945} - \cdots \right)
= \chi_{LA,1}H + \chi_{LA,3}H^3 + \chi_{LA,5}H^5 + \cdots. \tag{A3}
\]

The first term is the initial (linear) susceptibility, the second the cubic, and there on.

1. Linear response theory

The first linear response model to describe heat loss was probably described by Debye in the context of rigid electric dipoles. Here, we focus on the magnetic case. Let us start by assuming that a magnetic particle is subjected to a harmonic field \(H(t) = \Re e\{H_0 e^{\omega t}\} = H_0 \cos \omega t\), with the magnetic susceptibility \(\chi = \chi' - i\chi''\), where \(\chi'\) and \(\chi''\) correspond to the real and imaginary linear susceptibility terms, respectively. So, the magnetization term can be written as

\[
M(t) = \Re \{\chi H(t)\} = H_0 (\chi' \cos \omega t + \chi'' \sin \omega t),
\]

where \(\omega = 2\pi f\) with \(f\) the field frequency. Therefore, defining the heating efficiency (SLP) as the frequency times the hysteresis loss divided by the particle density (\(\rho\)) one finds

\[
SLP = \int \frac{f}{\rho V_p} \delta Q = -\int \frac{f}{\rho} \mu_0 \oint M dH
= \pi \frac{f}{\rho} \mu_0 H_0^2 \chi''. \tag{A4}
\]
This expression represents the heat loss of the magnetic material. So, one now needs an expression for the imaginary susceptibility term. If the projection of the magnetization, $M(t)$, in the field direction satisfies the Bloch equation, i.e., $\tau(dM/dt) + M = yH(t)$, where $\gamma$ is the magnetization relaxation time, one can show that the linear susceptibility term is $\chi = \chi_0/(1 + i\omega\tau)$, revealing that

$$\chi'' = \chi_0 \frac{\omega\tau}{1 + (\omega\tau)^2}. \quad (A5)$$

$\chi_0$ is the equilibrium susceptibility, which, in the absence of anisotropy contributions, i.e., within the Langevin model, is equal to $J_{LA,1}$. However, if anisotropy must be considered, this term would be different depending on energy symmetry and distinct particle configuration situations, e.g., longitudinal or random. The relaxation of the magnetization for a uniaxial nanoparticle is $\tau = \tau_0 e^{\sigma/\sigma_0}$ with $\sigma = KV/k_BT$, that is valid when $\sigma \geq 2$. Here, $V$ is the particle volume, $T$ is the temperature, $k_B$ is Boltzmann’s constant, and $K$ is the magnetic anisotropy. $\tau_0 = \sqrt{\pi}M_s(1 + \sigma^2)/(\gamma g_0 K\gamma)$ (about $10^{-10} - 10^{-8}$ s), with $\gamma g_0$ the electron gyromagnetic ratio and $\sigma$ the dimensionless damping factor. For the field applied in the anisotropy direction, one finds for the relaxation in the limit of high anisotropy

$$\tau_h = \frac{2\tau_0 [1 - h]e^{-\sigma(1-h)^2} + (1 + h) e^{-\sigma(1+h)^2}]^{-1}}{\sigma^{1/2}(1 - h^2)}. \quad (A6)$$

The field term $h$ is given in reduced units, i.e., $h = H_0/H_K$. This expression returns to the former in the absence of an applied field. The first one to describe this heat loss for magnetic fluids was Rosensweig. The above model predicts a loss proportional to the square of the applied field. However, this is only true experimentally at low field amplitudes as found in several cases dealing with magnetic nanoparticles. Note that the same issue occurs in the electric case for dielectrics or relaxor ferroelectrics. In addition, the LRT model predicts elliptical magnetic hysteresis curves, which have been observed at low field amplitudes (less than 4 kA/m) by Eggeman et al. and Tomitaka et al. However, this is not consistent with findings at higher field amplitudes, as for instance in magnetic particle imaging where a nonlinear response plays a crucial role.

2. Ferguson-Krishnan approach

In an attempt to include nonlinear phenomena in the description, Ferguson and Krishnan proposed a generalization of linear magnetization, using the Langevin function:

$$M(t) = M_S \left( 1 + \frac{1}{(1 + (\omega\tau)^2)} L(\xi \cos(\omega t)) + \frac{\omega\tau}{1 + (\omega\tau)^2} L(\xi \sin(\omega t)) \right). \quad (A7)$$

This approach assumes that the frequency response of higher field order (quasi-static) terms is the same as the linear dynamic susceptibility term and neglects the quasi-static contribution from the magnetic anisotropy energy term. This expression is usually used to obtain the nth-order harmonic magnetization, which represents an important quantity in magnetic particle imaging.

3. Raikher-Stepanov perturbation method

Using the perturbation theory, Raikher and Stepanov included the anisotropy term and showed that the magnetization could be written as $M(t) = \Re(\chi_3 H_0 e^{i\omega t} + \chi_3^* H_0 e^{-i\omega t} + \cdots)$. However, different from the FK model above, the frequency dependence of the cubic term was found to be different from the linear term. The authors found that the cubic susceptibility could be written as

$$\chi_3 = -\frac{1}{4} \frac{\chi^{(0)}_3}{\chi^{(0)}_1}(1 + S_2^2)(1 - i\omega\tau) \frac{(1 + 3\omega^2\tau^2 - 1)}{(1 + 3\omega^2\tau^2 - 5)}, \quad (A8)$$

where $\chi^{(0)}_3 = \phi M^3_0/\chi^{(0)}_1 S_2$. Here, $\phi$ is the particle volume fraction of the assembly, and $S_2 = (M^3_0/\chi^{(0)}_1) (3x^2 - 1) \exp(\sigma_3^2) dx/\chi^{(0)}_1 \exp(\sigma_3^2) dx$. So, the real and imaginary susceptibility terms are given by

$$\chi'_3 = \frac{1}{180} \frac{\chi^{(0)}_3}{\chi^{(0)}_1} \left( 1 + S_2^2 \right) (7\omega^2\tau^2 - 1), \quad (A9)$$

$$\chi''_3 = -\frac{1}{180} \frac{\chi^{(0)}_3}{\chi^{(0)}_1} \left( 1 + S_2^2 \right) \omega (3\omega^2\tau^2 - 5), \quad (A10)$$

Using up to the cubic term the magnetization of the nanoparticle in the RS model gives

$$M(t) = \left( \chi'_1 \cos(\omega t) + \chi''_1 \sin(\omega t) \right) H_0 + \left( \chi'_3 \cos(3\omega t) + \chi''_3 \sin(3\omega t) \right) H_0^3, \quad (A11)$$

where $\chi'_1 = \chi^{(0)}_1 (1 + 2S_2)/(1 + (\omega\tau)^2)$, $\chi''_1 = \omega\tau \chi^{(0)}_1 (1 + 2S_2)/(1 + (\omega\tau)^2)$, with $\chi^{(0)}_1 = \phi M^3_0 V/(k_BT)$ and $\chi'_3$ and $\chi''_3$ are given by Eqs. (A9) and (A10). Note that those expressions are valid for an ensemble and low field amplitudes. In order to obtain the equivalent expressions for the nanoparticle, one only needs to neglect the particle volume fraction in the equilibrium susceptibilities. The model is valid only at very low field amplitudes and shows an elliptical-like behavior as LRT (see below).

4. Stochastic Landau-Lifshitz-Gilbert model

The model that is expected to correctly describe the magnetization response of a single-domain nanoparticle at any field amplitude and frequency range is the SLLG model. In this case, the magnetic moment of the nanoparticle is assumed to be described by the Landau-Lifshitz-Gilbert equation

$$\frac{d\mathbf{M}}{dt} = -\gamma \mathbf{M} \times \mathbf{H}_{\text{eff}} - \frac{\chi''_1}{M_S} \mathbf{M} \times (\mathbf{M} \times \mathbf{H}_{\text{eff}}), \quad (A12)$$

where

$$\mathbf{H}_{\text{eff}}(t) = \mathbf{H}(t) + \mathbf{H}_{\text{an}} + \mathbf{H}_{\text{th}}(t). \quad (A13)$$
In this case, the effective field has three contributions: the applied external field, the anisotropy field, and the thermal fluctuation field. So the Landau-Lifshitz-Gilbert equation for a magnetic dipole is augmented with a Gaussian white noise thermal field $\vec{H}_{\text{th}}$ whose Cartesian coordinates satisfy the statistical properties: $\langle \vec{H}_{\text{th}}(t) \rangle = 0$ and $\langle \vec{H}_{\text{th}}(t) \vec{H}_{\text{th}}(s) \rangle = 2(k_B T / \mathcal{V}) \delta(t-s)$. The Kronecker and Dirac delta functions indicate that the thermal field is both spatial and temporally uncorrelated. In principle, one could use the equation above and do numerical simulations. However, the approach of Brown was to connect the SLLG equation to the Fokker-Planck equation of the magnetic moment orientation distribution function, which can be used to obtain the nanoparticle magnetic moment response.

In this work, we focus on the longitudinal case. The first authors to study in detail this problem analytically was Dejardin and Kalmykov. Later, others used the same approach to describe dynamic magnetic hysteresis. Here, the magnetic moment orientational distribution function $f(z, t)$ can be shown to obey the Fokker-Planck equation

$$2 \tau_N \frac{\partial f}{\partial t} = \frac{\partial}{\partial z} \left[ (1 - z^2) \left( \frac{\partial f}{\partial z} - f z h_{\text{eff}}(z, t) \right) \right],$$  \quad (A14)$$

with $\tau_N = (1 + z^2) / \tau_0$, the free diffusion time and $z = \cos \theta$ with $\theta$ the angle between the magnetic dipole and the applied field. The magnetic anisotropy is assumed uniaxial. So, the ratio of the particle energy to thermal energy can be written as

$$\frac{U_{\text{eff}}}{k_B T} = -\sigma z^2 - 2h \sigma z,$$  \quad (A15)$$

where the field term $h = H / H_K$. Therefore, the effective field is

$$h_{\text{eff}} = - \frac{1}{k_B T} \frac{\partial U_{\text{eff}}}{\partial z} = 2\sigma (h + z).$$  \quad (A16)$$

The Fokker-Planck equation is then used to obtain the time evolution of the $l$th-order moment $p_l(t) = \langle P_l \rangle$, which is shown to be described by

$$2 \tau_N \frac{dp_l}{dt} = \frac{l(l + 1)}{2l + 1} (A_1 + A_2) - l(l + 1) p_l,$$  \quad (A17)$$

with

$$A_1 = 2\sigma h (p_{l-1} + p_{l+1}),$$  \quad (A18)$$

and

$$A_2 = 2\sigma \left[ \frac{l - 1}{2l - 1} p_{l-2} + \frac{2l + 1}{(2l - 1)(2l + 3)} p_l - \frac{l + 2}{2l + 3} p_{l+2} \right].$$  \quad (A19)$$

This equation shows that each moment depends on others in a nonlinear fashion. This infinite hierarchy may be solved numerically using fast sparse solvers and discarding several periods of the external field. Alternatively, one could also expand the $p_l(t)$ in a Fourier series as

$$p_l(t) = \sum_{k=-\infty}^{\infty} F_k^l(\omega) e^{i\omega t},$$  \quad (A20)$$

with all $p_l(t)$ real, which implies that $F_{l-k}^l = (F_k^l)^*$, where the asterisks refer to the complex conjugate. This will then lead to a hierarchy of algebraic equations for the Fourier amplitudes, which also need to be solved numerically.

5. Magnetization loops

We are now in condition to compare the hysteresis loops of each model, namely, the linear response theory using the field-independent relaxation time (LRT) and also the field-dependent relaxation time of Eq. (A6) (LRT $\tau_b$), the FK model, the RS model, and the exact solution for the SLLG model. In Fig. 5(a), we show the magnetization curves of all those models. It is clear that the LRT model, independent of the relaxation time equation used, shows an elliptical loop. The RS model showed a similar behavior. The only model that shows a significant difference from LRT is the FK model. However, it also shows an elliptical hysteresis, which

![FIG. 5. (a) Dynamic hysteresis curves for the LRT, LRT considering field dependence on relaxation time $\tau$, Ferguson-Krishnan approach, Raiker Stepanov method, and numerical solution of SLLG for $\sigma = 6$ and $\sigma T_0 = 10^{-3}$. (b) Longitudinal to Langevin susceptibilities ratio for $n = 1$, $n = 3$, and $n = 5$.](image-url)
is distinct from the LRT model because of the Langevin equilibrium susceptibility. So, different from the other models, it does not take into account the anisotropy term. Nevertheless, for the parameters used in this simulation, it is shown that none of the models above represent well the exact solution given by the SLLG magnetization hysteresis loop. Although improvements were obtained in each model, in general they are not yet satisfactory. The importance of anisotropy in magnetic response description becomes clear on the other hand, it tends to the Ising behavior, in high anisotropy limit, when the ratio approaches 3.
